ABSTRACT

We investigate the cosmological constraints from the void-lensing cross-correlation assuming the w CDM model for the Chinese Space Station Survey Telescope (CSST) photometric survey. Using Jiutian simulations, we construct a mock galaxy catalog to $z = 3$ covering 100 deg^2 which incorporates the instrumental and observational effects of the CSST. We divide the galaxy sample into seven photometric-redshift (photo- z) tomographic bins and identify 2D voids within each bin using the Voronoi tessellation and watershed algorithm. We measure the angular cross-power spectrum between the void distribution and the weak lensing signal, and estimate the covariance matrix via jackknife resampling combined with pseudo- C_ℓ approach to account for the partial sky correction. We employ the Halo Void Dust Model (HVDM) to model the void-matter cross-power spectrum and adopt the Markov Chain Monte Carlo (MCMC) technique to implement the constraints on the cosmological and void parameters. We find that our method can accurately extract the cosmological information, and the constraint accuracies of some cosmological parameters from the void-lensing analysis are comparable or even tighter than the weak lensing only case. This demonstrates that the void-lensing serves as an effective cosmological probe and a valuable complement to galaxy photometric surveys, particularly for the Stage-IV surveys targeting the high-redshift Universe.

Keywords: Cosmology (343) —Cosmological parameters (339) — Large-scale structure of the universe (902) — Dark matter (353) —Voids (1779)

1. INTRODUCTION

The accurate measurements of temperature fluctuations of the cosmic microwave background (CMB) (G. Hinshaw et al. 2013; Planck Collaboration et al. 2020; S. Aiola et al. 2020), together with the discovery of the accelerating expansion of the Universe by Type Ia supernova (SN Ia) observations (A. G. Riess et al. 1998; S. Perlmutter et al. 1999), have provided important observational evidence for the establishment of the standard cosmological model. This model describes a spatially

flat universe composed of roughly 30% matter and 70% dark energy, whose nature remains poorly understood and continues to be one of the main challenges in modern cosmology. The large-scale structure (LSS) of the Universe, arising from the gravitational growth of primordial density fluctuations, provides a powerful set of tools to probe dark matter and dark energy, which can effectively complement the measurements of SN Ia and CMB (T. M. C. Abbott et al. 2022).

Weak gravitational lensing (WL), which refers to slight distortions of distant background galaxies induced by the gravitational potential along the line of sight, has become a powerful probe of the LSS (M. Bartelmann & P. Schneider 2001). It enables direct mapping of the

dark matter distribution and reveals the influence of dark energy on the growth of structure (M. Kilbinger 2015). In particular, measurements of the two-point correlation function or the angular power spectrum of the weak lensing signal, known as cosmic shear, provide stringent constraints on the key cosmological parameters, especially the total matter density parameter Ω_m and the amplitude of matter fluctuations σ_8 (H. Hildebrandt et al. 2017; J. L. van den Busch et al. 2022; A. H. Wright et al. 2025; M. A. Troxel et al. 2018; A. Amon et al. 2022; C. Doux et al. 2022). Moreover, combinations of weak lensing and other tracers of the LSS, such as galaxy clustering (the so-called 3×2 pt probes), offer the means of breaking degeneracies between the parameters, mitigating the systematic effects and therefore enhancing cosmological constraints (T. M. C. Abbott et al. 2018, 2022; E. van Uitert et al. 2018; C. Heymans et al. 2021; B. Joachimi et al. 2021).

Recently, cosmic voids, which are large and underdense regions within the cosmic web, have emerged as a promising cosmological probe for studying the LSS (R. van de Weygaert & E. van Kampen 1993; D. C. Pan et al. 2012; A. Pisani et al. 2019; M. Moresco et al. 2022; N. Schuster et al. 2025; Y. Song et al. 2025b). Owing to their low-density environment, void formation and evolution are sensitive to the dark energy equation of state and the total neutrino mass (R. Biswas et al. 2010; G. Lavaux & B. D. Wandelt 2012; A. Pisani et al. 2015; J. Lee & D. Park 2009; E. Massara et al. 2015; C. D. Kreisch et al. 2019). Their statistics, such as the void shapes, the void density profile and the void size function (VSF), have already been employed to constrain the cosmological parameters (G. Lavaux & B. D. Wandelt 2010; C. M. Correa et al. 2021; Y. Song et al. 2024a,b, 2025b; K. Lehman et al. 2025). Additionally, several studies have explored the correlation function of cosmic voids and their cross-correlations with other cosmological probes (B. R. Granett et al. 2008; N. Hamaus et al. 2014b; C. M. Correa et al. 2022; K. C. Chan et al. 2014; Y. Song et al. 2024c, 2025a).

In particular, it is possible to measure the cross-correlation between void and weak lensing, and exploit this signal to infer cosmological information, and break the parameter degeneracy (E. Krause et al. 2013; P. Melchior et al. 2014; C. Sánchez et al. 2017; Y. Fang et al. 2019; M. Bonici et al. 2023; C. Su et al. 2025). In this work, we investigate the cosmological constraint power of the void-lensing cross-power spectrum in the photometric survey of the Chinese Space Station Survey Telescope (CSST, H. Zhan 2011; H. Zhan 2021; Y. Gong et al. 2019, 2025; CSST Collaboration et al. 2025).

We construct a mock galaxy catalog covering a sky area of $\sim 100 \text{ deg}^2$ based on the Jiutian simulations (J. Han et al. 2025), taking into account the instrumental design and survey strategy of the CSST photometric survey. From this mock catalog, we derive the galaxy redshift distribution and divide it into seven photometric-redshift (photo- z) tomographic bins. We apply the Voronoi tessellation and watershed algorithm to identify voids in the two-dimensional angular galaxy distribution within each tomographic bin and obtain the void catalog. Then we measure the angular cross-power spectrum between the void distribution and the weak lensing signal. Covariance estimation is performed using the jackknife method combined with the pseudo- C_ℓ approach. Finally, we constrain cosmological and systematic parameters using the Markov Chain Monte Carlo (MCMC) method.

This paper is organized as follows. In Section 2, we introduce the construction of the mock galaxy and void catalogs for the CSST photometric survey, and describe the measurement of the void lensing power spectrum. Section 3 presents the theoretical modeling of the angular power spectrum, including the treatment of relevant systematics. The covariance estimation, the model fitting method and the discussion of constraints on the cosmological and systematic parameters are given in Section 4. Our conclusions are summarized in Section 5.

2. MOCK DATA

2.1. Simulation

We employ the Jiutian-1G (JT1G) simulation to serve as the basis for constructing the weak lensing convergence map and generating the mock galaxy catalog. JT1G is one of the high-resolution runs in the state-of-the-art Jiutian N-body simulation suite. It is performed with the L-Gadget3 code (V. Springel 2005) and evolves 6144^3 dark matter particles within a cubic simulation box. The box size is $1h^{-1}\text{Gpc}$ and the particle mass is about $3.72 \times 10^8 h^{-1} M_\odot$. We adopt the cosmological parameters from *Planck*2018 (Planck Collaboration et al. 2020), with $\Omega_m = 0.3111$, $\Omega_b = 0.0490$, $\Omega_\Lambda = 0.6899$, $\sigma_8 = 0.8102$, $n_s = 0.9665$, and $h = 0.6766$. The JT1G simulation outputs 128 snapshots from redshift 127 to 0 with an average time gap of $\sim 100 \text{ Myr}$, which is suitable for weak lensing studies. The dark matter halos and subhalos are identified using the friend-of-friends (FOF) and SUBFIND algorithm (V. Springel 2005). Additionally, the subhalos are linked with their unique descendants to establish the merger trees. Further details of JT1G can be found in J. Han et al. (2025).

Considering the effects of structure evolution, we construct a partial-sky light cone with a set of discrete slices

Figure 1. The mock galaxy redshift distributions in the CSST photometric survey. The solid curves denote the redshift distributions of the seven photo- z bins, which are obtained by stacking samples drawn from the redshift PDF of each individual galaxy.

based on the outputting snapshots at different redshifts. To dilute the structure repetitions caused by box replication, a specific viewing angle is chosen as the line-of-sight (LOS) direction, producing a light cone that extends to $z = 3$ and covers a sky area of 100 deg^2 , which is sufficient for the purposes of this study. The light-cone construction for both dark matter particles and halos (or galaxies) follows the same strategy, ensuring that different tracers capture identical cosmological information (see e.g. Q. Xiong et al. 2025).

2.2. Galaxy Mock Catalog

We populate the simulations with galaxies utilizing an improved Semi-Analytic Model (B. M. B. Henriques et al. 2015; W. Pei et al. 2024), which provides a variety of observational properties including galaxy spectral-energy distribution (SED), emission lines, and apparent magnitudes. Galaxy samples are then selected according to the apparent magnitude limits of the CSST photometric survey, which can reach $i \sim 26$ AB mag for 5σ point source detection (Y. Gong et al. 2019; CSST Collaboration et al. 2025). To estimate photometric redshifts, we assume that the observed redshift of each galaxy follows a Gaussian probability distribution function (PDF), $z_{\text{obs}} \sim N(z_{\text{true}}, \sigma_z)$, where z_{true} is the true redshift and σ_z represents the redshift uncertainty characterized as $\sigma_z = \sigma_{z_0}(1 + z)$ with $\sigma_{z_0} = 0.05$ (Y. Gong et al. 2019). The resulting photo- z distribution from the mock catalog can be obtained by stacking samples drawn from the redshift PDFs of individual galaxies. In Figure 1, we show the redshift distributions of the seven photo- z bins in the CSST photometric survey.

Table 1. The CSST galaxy and void samples used in this work. The photo- z tomographic bins, number of galaxies and voids in each bin (N_g and N_v), and the average surface number density of galaxies and voids in arcmin^{-2} ($\bar{n}_g$ and $\bar{n}_v$) have been listed.

redshift bin	N_g	$\bar{n}_g$	N_v	$\bar{n}_v$
$0.45 < z \leq 0.61$	1090894	3.03	35732	0.099
$0.61 < z \leq 0.78$	1217180	3.38	40434	0.112
$0.78 < z \leq 0.98$	1298654	3.61	43499	0.121
$0.98 < z \leq 1.20$	1137921	3.16	76719	0.213
$1.20 < z \leq 1.50$	1116709	3.10	25961	0.072
$1.50 < z \leq 1.90$	1054731	2.93	20488	0.057
$1.90 < z \leq 3.00$	904882	2.51	12613	0.035

We mimic weak lensing distortions, including convergence κ and shear $\gamma = \gamma_1 + i\gamma_2$, using the multi-lens-plane algorithm implemented in LensTools⁷ (S. Hilbert et al. 2009; A. Petri 2016). Dark matter particles in the light cone are divided into discrete slices, and light rays are traced from the observer to the source planes to compute deflections and generate synthetic lensing maps. Note that since the resulting maps reside on an observer grid, we shift galaxies to their apparent positions via lensing deflections, and then assign lensing quantities to each galaxy based on its redshift and apparent position (Q. Xiong et al. 2025).

2.3. Void Mock Catalog

We adopt the Voronoi tessellation and watershed algorithm to identify voids in the 2D angular distribution of galaxies within projected slices, which have been widely employed in 3D void identification (M. C. Neyrinck 2008; P. M. Sutter et al. 2015; S. Nadathur et al. 2019). To ensure that most galaxies will be assigned to the correct slice, the line-of-sight width of each slice should be sufficiently large, at least about twice the photo- z uncertainty. Specifically, we divide the galaxy sample into seven photo- z tomographic bins, each containing similar numbers of galaxies. The bin edges are defined by the endpoints $\{z_e\} = \{0.45, 0.61, 0.78, 0.98, 1.20, 1.50, 1.90, 3.0\}$, as presented in Table 1. This binning strategy aims to extract more information and mitigates the overlap of 2D voids across slices. Here we focus on the redshift range $z = 0.45 - 3.0$ for our analysis, since the LSS at lower redshifts is well-measured by spectroscopic surveys and galaxy density

Figure 2. Schematic illustration of the procedure for identifying 2D voids from the galaxy catalog. (a) A slice of galaxies from a small region of the mock catalog, where black dots indicate galaxy positions. (b) The 2D Voronoi tessellation constructed from the galaxy distribution, with each galaxy assigned to a Voronoi cell. (c) Voronoi cells colored by the local density. (d) Identified zones (2D void candidates without pruning), where crosses mark the cores (local density minima) of the zones and colors distinguish different zones.

decreases rapidly at higher redshifts in the CSST photometric survey (Y. Gong et al. 2019; Y. Song et al. 2025a; Q. Xiong et al. 2025).

The algorithm begins by producing a Voronoi tessellation of the galaxy sample, which partitions space into cells around each galaxy. Each cell includes a single galaxy and is defined as the region of space closer to that galaxy than to any other in the sample. The den-

sity within each cell is then estimated as $\rho_{\text{cell}} = 1/S_{\text{cell}}$, where S_{cell} denotes the cell area determined by Voronoi tessellation. The Voronoi tessellation also provides a natural set of neighbors for each galaxy, which can be used to identify local density minima. Zones are then built from each density minimum in the distribution of cells using a watershed algorithm, where each cell is linked to its least dense neighbor and merged

accordingly, repeating the process until it arrives at a minimum. Finally, voids are formed by identifying low-density boundaries (saddle points) between adjacent zones and merging them into larger unions of separated regions. In Figure 2, we illustrate the procedure for identifying 2D voids from the galaxy catalog.

In 3D void identification, various combinations of zones may be defined as voids, and there exist different treatments for combining zones, referred to as pruning methods (H. Rincon et al. 2025). To determine which zones should be combined into definitive voids in our 2D void identification, we apply a pruning procedure similar to the VIDE method (P. M. Sutter et al. 2015). Specifically, we combine adjacent zones into a void if density of the boundaries between them is less than 0.4 times the average density, and remove voids with central-density greater than 0.4 times the average density. The angular radius of a void θ_v is then derived from an effective circle whose area S_v equals the total area of all cells comprising the void, which is given by

$$S_v = \sum_i S_{\text{cell}}^i = \pi \theta_v^2, \quad (1)$$

where S_{cell}^i denotes the area of the cell i . The void position is characterized by its area-weighted center $\mathbf{X}_v$, which is calculated from its constituent cells as

$$\mathbf{X}_v = \frac{1}{S_v} \sum_i \mathbf{x}_i S_{\text{cell}}^i, \quad (2)$$

where $\mathbf{x}_i$ is the coordinate of the galaxy within the cell i .

2.4. Void-Lensing Power Spectrum Measurement

Having obtained the mock catalogs, we can measure the angular cross-power spectrum between the void distribution and the weak lensing signal. We first construct the tomographic shear maps by projecting the shear values of each galaxy onto a two-dimensional Cartesian grid using the formula

$$\hat{\gamma}_p(\boldsymbol{\theta}) = \frac{\sum_{i \in p} w_i \hat{\gamma}_i(\boldsymbol{\theta})}{\sum_{i \in p} w_i}, \quad (3)$$

where the index i runs over galaxies in the catalog, p denotes the map pixels, $\hat{\gamma}_i = (\hat{\gamma}_{1,i}, \hat{\gamma}_{2,i})$ is the shear of the i -th galaxy, $\boldsymbol{\theta}$ represents the angular coordinates on the sky, and w_i is the associated weight. For simplicity, we set $w_i = 1$ for all galaxies. The shear field is then converted into a lensing convergence field via the Kaiser-Squires inversion (N. Kaiser & G. Squires 1993), which is expressed as

$$\tilde{\kappa}(\boldsymbol{\ell}) = \left(\frac{\ell_1^2 - \ell_2^2}{\ell_1^2 + \ell_2^2} \right) \tilde{\gamma}_1(\boldsymbol{\ell}) + 2 \left(\frac{\ell_1 \ell_2}{\ell_1^2 + \ell_2^2} \right) \tilde{\gamma}_2(\boldsymbol{\ell}), \quad (4)$$

where $\boldsymbol{\ell} = (\ell_1, \ell_2)$ denotes the multipoles in Fourier space, and $\tilde{\kappa}$ and $\tilde{\gamma} = (\tilde{\gamma}_1, \tilde{\gamma}_2)$ are the Fourier transforms of the convergence κ and shear γ fields, respectively. The real space convergence map is then obtained by performing the inverse fast Fourier transform of $\tilde{\kappa}$.

On the other hand, the tomographic void overdensity map can be obtained by

$$\delta_p = \frac{N_p \sum_{p'} A_{p'}}{A_p \sum_{p'} N_{p'}} - 1, \quad (5)$$

where $N_p = \sum_{i \in p} v_i$ is the number of voids at a given pixel p , A_p is the effective fraction of the area at pixel p .

We derive the mock angular cross-power spectrum from the void density maps and weak lensing convergence maps at $\ell < 1500$. The results are shown in Figure 3, along with the theoretical prediction calculated using the w CDM best-fitting parameters. The covariance matrix is estimated using the jackknife method combined with the pseudo- C_ℓ approach (P. J. E. Peebles 1973; E. Hivon et al. 2002; G. Chon et al. 2004), as implemented in NAMASTER code⁸ (D. Alonso et al. 2019). The details of the covariance estimation are provided in Section 4.1.

3. THEORETICAL MODELING

Under the flat sky assumption and the Limber approximation (D. N. Limber 1954), the angular power spectrum $C_{AB}^{ij}(\ell)$ between the i -th tomographic bin of probe A and j -th tomographic bin of probe B can be expressed as

$$C_{AB}^{ij}(\ell) = \int d\chi \frac{q_A^i(\chi) q_B^j(\chi)}{\chi^2} P_{AB} \left(\frac{\ell + 1/2}{\chi}, \chi \right), \quad (6)$$

where A and B denote two different types of tracers, χ is the comoving radial distance, $q^i(\chi)$ is the weighting function of the i -th tomographic bin, and P_{AB} denotes the probe-dependent power spectrum.

For the case of voids and weak lensing, P_{AB} corresponds to the void-matter cross-power spectrum P_{vm} , which is modeled using the Halo Void Dust Model (HVDM) (R. Voivodic et al. 2020). The fundamental assumption of HVDM is that all matter in the Universe belongs to dark matter halos, cosmic voids, and ‘dust’, which refers to linear matter field between halos and voids. Accordingly, the matter density field can be de-

⁸ <https://github.com/LSSTDESC/NaMster>

Figure 3. The mock CSST void-lensing cross-power spectra for the seven tomographic bins in 100 deg^2 . The blue solid curves show the results of the best-fitting theoretical model, and the data points are the mock data. The blue data points denote the signal-to-noise ratio (SNR) < 1 , which are discarded in the constraint process. The gray regions show the small scales that are excluded with $k_{\text{max}} = 0.3 \text{ Mpc}^{-1}h$. We also discard the cross-power spectra with low amplitudes, and only consider the void-lensing power spectrum for the case $i < j$ in the analysis, where i and j denote the tomographic bins of the void and weak lensing samples, respectively

composed as

$$\rho(\mathbf{x}) = \sum_i^{\text{halos}} \rho_h(\mathbf{x} - \mathbf{x}_i | M_i) + \sum_j^{\text{voids}} \rho_v(\mathbf{x} - \mathbf{x}_j | M_j) + \rho_d(\mathbf{x}), \quad (7)$$

where $\rho_h(\mathbf{x} - \mathbf{x}_i | M_i)$ is the density profile of a halo with mass M_i centered at position $\mathbf{x}_i$, $\rho_v(\mathbf{x} - \mathbf{x}_j | M_j)$ is the density profile of a void with mass M_j centered at position $\mathbf{x}_j$, and $\rho_d(\mathbf{x})$ is the dust density.

In Fourier space, the void-matter power spectrum can be decomposed into contributions from 1-Void, 2-Void, Halo-Void and Void-Dust terms, which is expressed as

$$P_{vm}(k|M) = P_{vm}^{1V}(k|M) + P_{vm}^{2V}(k|M) + P_{vm}^{HV}(k|M) + P_{vm}^{VD}(k|M). \quad (8)$$

If we consider large scales, we can simplify the 2-Void, Halo-Void and Void-Dust terms and obtain (R. Voivodic et al. 2020)

$$P_{vm}(k|R) = P_{vm}^{1V}(k|R) + b_v(R)P_{mm}^L(k), \quad (9)$$

where b_v denotes the void bias, P_{mm}^L is the linear matter power spectrum computed using CAMB (A. Lewis et al. 2000), and P_{vm}^{1V} represents the 1-Void term present in the HVDM, which is given by

$$P_{vm}^{1V} = \frac{M}{\bar{\rho}_m} u_v(k|M), \quad (10)$$

where u_v is the Fourier transform of the void profile

$$u_v(k|M) = \int_0^{r_v} \frac{4\pi r^2}{M} \frac{\sin kr}{kr} \rho_v(r|M) dr. \quad (11)$$

Here we adopt the Hamaus-Sutter-Wandelt (HSW) profile (N. Hamaus et al. 2014a), and it is given by

$$\frac{\rho_v(r)}{\bar{\rho}_m} - 1 = \delta_c \frac{1 - (r/r_s)^\alpha}{1 + (r/r_v)^\beta}, \quad (12)$$

where δ_c is the central density contrast, $r_s \equiv \gamma r_v$ is the scale radius at which $\rho_v = \bar{\rho}_m$, and α and β determine the inner and outer slopes of the void compensation wall, respectively. These four parameters ($\delta_c, \alpha, \beta, \gamma$) are treated as free parameters in our fitting procedure. For simplicity, we use the mean void radius $R_v^{\text{mean}} = \theta_v^{\text{mean}} D_A$ in our calculation, where D_A is the comoving angular diameter distance of each tomographic bin.

The weighting functions of void and weak lensing are given by

$$q_v^i(\chi) = n_v^i(z(\chi)) \frac{dz}{d\chi}, \quad (13)$$

$$q_\kappa^i(\chi) = \frac{3H_0^2\Omega_m}{2c^2} \frac{\chi}{a(\chi)} \int_\chi^\infty d\chi' n_g^i(z(\chi')) \frac{dz}{d\chi'} \frac{\chi' - \chi}{\chi'}, \quad (14)$$

where n_v^i is the normalized void redshift distribution in the i -th tomographic bin, H_0 is the Hubble constant, Ω_m is the matter density, c is the speed of light, $a(\chi)$ is the scale factor corresponding to the comoving distance χ , and n_g^i is the normalized redshift distribution of the source galaxies of the tomographic bin i .

When modeling the redshift distribution $n_g^i(z)$, we account for possible uncertainties by introducing shift parameter Δz^i and stretch parameter σ_z^i as free parameters (R. Cawthon et al. 2022; A. Porredon et al. 2022). The modified redshift distribution is then given by

$$n_g^i(z) \rightarrow \frac{n_g^i}{\sigma_z^i} \left(\frac{z - \langle z^i \rangle - \Delta z^i}{\sigma_z^i} + \langle z^i \rangle \right), \quad (15)$$

where $\langle z^i \rangle = \int z n_g^i(z) dz / \int n_g^i(z) dz$ denotes the mean redshift of the i -th tomographic bin.

To account for uncertainties in shear estimation, we introduce multiplicative factors to the weak lensing weighting function as

$$q_\kappa^i(\chi) \rightarrow (1 + m^i) q_\kappa^i(\chi), \quad (16)$$

where m^i represents the shear calibration bias for the i -th source bin. Furthermore, since the measured cross-power spectra are subject to both statistical and systematic uncertainties, we model these uncertainties by incorporating a noise term, leading to

$$\tilde{C}_{v\kappa}^{ij}(\ell) = C_{v\kappa}^{ij}(\ell) + N_{v\kappa}^{ij}, \quad (17)$$

where $N_{v\kappa}^{ij}$ denotes the noise contribution, which we treat as free parameters in the constraint process. For

simplicity, we neglect the contribution from intrinsic alignments in the void-lensing cross-correlation (M. Bonici et al. 2023).

Equations (13) and (14) indicate that the lensing kernel of a high-redshift bin has a large overlap with the void weighting function of the low-redshift bin. Moreover, the weak lensing signal is the accumulative effect along the LOS, and we expect a strong correlation between the background cosmic shear and the foreground void clustering. Therefore, we only consider the void-lensing power spectra for the case $i < j$ to perform the cosmological analysis, as shown in Figure 3, where i and j denote the tomographic bins of the void and weak lensing samples, respectively.

Since the void model is valid on large scales, we apply a scale cut procedure in our void lensing analysis analogous to that used in galaxy-galaxy lensing to mitigate modeling uncertainties at small scales. Specifically, we only consider the multipoles that satisfy $\ell \leq k_{\text{max}} \chi \langle \langle z^i \rangle \rangle$ and adopt $k_{\text{max}} = 0.3 \text{ Mpc}^{-1} h$.

4. CONSTRAINT AND RESULTS

4.1. Covariance Estimation

The covariance matrix and more specifically its inverse, i.e. the precision matrix, is the key quantity that determines the uncertainties on cosmological parameters. In general, it can be estimated through three approaches: estimation from numerical simulations, analytical modeling/computation, and direct estimation from the data (E. Krause et al. 2017). Here we adopt the third option and estimate the covariance using jackknife resampling.

To compute the jackknife covariance, we first construct a set of jackknife samples by systematically excluding one jackknife segment at a time and using the remaining data to measure the angular power spectrum. However, this procedure inevitably introduces a systematic bias due to the altered survey footprint. This is because the ‘excluding one segment’ operation is equivalent to applying a mask to the map, which leads to mode coupling in the power spectrum. To account for this effect, we estimate the angular power spectrum of each jackknife realization using the so-called pseudo- C_ℓ method (P. J. E. Peebles 1973; E. Hivon et al. 2002; G. Chon et al. 2004), which is implemented in NAMASTER code (D. Alonso et al. 2019).

Figure 4. The normalized full covariance matrix, shown in terms of the correlation coefficient $C_{ij}/\sqrt{C_{ii}C_{jj}}$, where C_{ij} are the elements of the covariance matrix, estimated from jackknife realizations. The $C_{v\kappa}$ values in the data vector are ordered according to their redshift bin combinations (m, n) .

The estimator of the covariance matrix is then given by

$$\text{Cov}_{\text{JK}}^{ijmn}(\ell_1, \ell_2) = \frac{N_{\text{JK}} - 1}{N_{\text{JK}}} \sum_{k=1}^{N_{\text{JK}}} (C_k^{ij}(\ell_1) - \bar{C}^{ij}(\ell_1))^T \times (C_k^{mn}(\ell_2) - \bar{C}^{mn}(\ell_2)), \quad (18)$$

where superscript i, j, m, n label the tomographic bins and in combination represent the cross-spectrum between two tomographic bins, N_{JK} is the number of jackknife samples. To ensure the covariance matrix is non-singular, N_{JK} must be greater than the length of the data vector (Euclid Collaboration et al. 2025; M. J. Looijmans et al. 2025). Here $C_k^{ij}(\ell)$ denotes the angular power spectrum measured for the k -th jackknife realization, and $\bar{C}^{ij}(\ell)$ is the mean spectrum over all jackknife samples, which is given by

$$\bar{C}^{ij}(\ell) = \frac{1}{N_{\text{JK}}} \sum_{k=1}^{N_{\text{JK}}} C_k^{ij}(\ell). \quad (19)$$

In Figure 4, we show the normalized covariance matrix estimated from the jackknife realizations, where the block structure reflects correlations among different tomographic bin combinations and multipole ranges.

From Equation (18), we can obtain the precision matrix estimator (J. Hartlap et al. 2007)

$$\text{Cov}^{-1} = \frac{N_{\text{JK}} - d - 2}{N_{\text{JK}} - 1} \text{Cov}_{\text{JK}}^{-1}, \quad (20)$$

Table 2. The fiducial values and priors of the free parameters considered in the constraint process. Uniform priors are described by $\mathcal{U}(x, y)$, with x and y denoting the prior range. The Gaussian priors are represented by $\mathcal{N}(\sigma, \mu)$, and σ and μ are the mean and standard deviation, respectively.

Parameter	Fiducial Value	Prior
Cosmology		
h	0.6766	$\mathcal{U}(0.4, 1.0)$
Ω_m	0.3111	$\mathcal{U}(0.1, 0.6)$
$10^9 A_s$	2.03	$\mathcal{U}(0.5, 5.0)$
n_s	0.9665	$\mathcal{U}(0.5, 1.5)$
w	-1	$\mathcal{U}(-1.8, 0.2)$
Void profile		
α^i	-	$\mathcal{U}(0, 10)$
β^i	-	$\mathcal{U}(0, 20)$
γ^i	-	$\mathcal{U}(0, 5)$
δ_{cen}^i	-	$\mathcal{U}(-1, -0.5)$
Void bias		
b_v^i	-	$\mathcal{U}(0, 5)$
Photo-z shift		
Δz^i	(0, 0, 0, 0, 0, 0)	$\mathcal{U}(-0.1, 0.1)$
Photo-z stretch		
σ_z^i	(1, 1, 1, 1, 1, 1)	$\mathcal{U}(0.5, 1.5)$
Shear calibration		
m^i	(0, 0, 0, 0, 0, 0)	$\mathcal{N}(0, 0.01)$
Noise		
$10^{10} N_{v\kappa}^{ij}$	-	$\mathcal{U}(-100, 100)$

where the prefactor corrects for the multiplicative bias resulting from the inversion of the covariance matrix estimator, and d is the length of the data vector.

4.2. Fitting Method

We employ the χ^2 statistic method to fit the mock data of void-lensing cross-power spectrum, which is given by

$$\chi^2 = (\mathbf{D} - \mathbf{M}(\mathbf{p})) \text{Cov}^{-1} (\mathbf{D} - \mathbf{M}(\mathbf{p})), \quad (21)$$

where $\mathbf{D}$ denotes the data vector of the void-lensing power spectrum, $\mathbf{M}(\mathbf{p})$ represents the corresponding theoretical model prediction with parameters $\mathbf{p}$, and Cov^{-1} is the precision matrix estimated from Equation (20). The likelihood function can then be calculated by $\mathcal{L} \sim \exp(-\chi^2/2)$.

Figure 5. Constraints on the five cosmological parameters derived from the CSST void-lensing analysis over a 100 deg² survey area. The shaded regions represent the 1 σ (68.3%) and 2 σ (95.5%) confidence levels. The vertical and horizontal dotted lines indicate the fiducial values of these parameters.

We utilize `emcee`⁹ (D. Foreman-Mackey et al. 2013), a robust and well-tested Python implementation of the affine-invariant ensemble sampler for the MCMC proposed by J. Goodman & J. Weare (2010), to perform the parameter constraints. The free parameters, along with their fiducial values and prior assumptions, are summarized in Table 2. The free cosmological parameters include the reduced Hubble constant h , total matter density parameter Ω_m , amplitude of the initial power spectrum A_s , spectral index n_s and dark energy equation of state w . Since both void and weak-lensing observables are insensitive to the baryon density parameter Ω_b , we fix it to the value adopted in the JT1G simulation.

⁹ <https://github.com/dfm/emcee>

In addition, we include a set of void parameters, i.e. the void bias b_v^i and the void profile parameters α^i , β^i , γ^i , and δ_{cen}^i as free parameters for each redshift bin. The multiplicative factors m^i , photo- z uncertainties Δz^i and σ_z^i , and noise term $N_{\text{v}\kappa}^{ij}$ are also considered in our fitting process. We adopt flat priors for cosmological parameters, void bias, void profile parameters, and photo- z uncertainties. The Gaussian priors are imposed on the shear calibration parameters, assuming that the CSST photometric survey can offer high imaging quality and excellent control over systematic uncertainties (see e.g. Y. Gong et al. 2019; CSST Collaboration et al. 2025).

4.3. Constraint Results

In Figure 5, we present the marginalized two-dimensional contours and one-dimensional posterior dis-

Figure 6. The best-fitting values and corresponding 1σ constraints of the parameters α^i , β^i , γ^i , and δ_{cen}^i derived from the void lensing analysis.

tributions (PDFs) of the five cosmological parameters constrained from the void-lensing analysis, with the 68.3% and 95.5% confidence levels (CLs). The vertical and horizontal dashed lines indicate the fiducial values of the parameters.

We find that the cosmological parameters can be robustly constrained using the mock data within a 100 deg^2 survey area, and the fitting results of the cosmological parameters are consistent with the fiducial values within the 1σ CL. For the key parameters h , Ω_m and w , we obtain constraint accuracies of 18%, 22% and 33%, respectively, corresponding to $h = 0.63^{+0.10}_{-0.13}$, $\Omega_m = 0.296^{+0.049}_{-0.079}$ and $w = -1.12^{+0.39}_{-0.34}$. The constraint results of these cosmological parameters are comparable (e.g. Ω_m , w) or even tighter (e.g. h) than those from the weak lensing only analysis presented in Q. Xiong et al. (2025), which used the same mock galaxy catalog.

These results demonstrate that our two-dimensional void identification method can reliably construct the 2D void catalog, and the theoretical model can accurately extract cosmological information from the void-lensing correlation. We note that the current constraint accuracies derived from the mock data are limited by the sky area of the light-cone (100 deg^2). For the full CSST photometric survey with 17,500 deg^2 coverage, the constraints are expected to improve by about an order of magnitude, resulting in accuracies of a few percent-level accuracy.

In Figure 6, we show the best-fitting values and corresponding 1σ uncertainties for the parameters α^i , β^i , γ^i , and δ_{cen}^i . Overall, the parameters are well constrained,

Figure 7. The contour maps (68.3% and 95.5% CLs) and 1D PDFs of the void bias for the six tomographic bins from the CSST void-lensing analysis over a 100 deg^2 survey area.

with most exhibiting relatively small uncertainties compared to their best-fitting amplitudes. For the α^i and β^i parameters, the best-fitting values are clustered around 1–5 and 6–10, respectively, indicating stable and consistent constraints across the six bins. The γ^i parameters exhibit comparatively larger fractional uncertainties, suggesting weaker sensitivity or stronger degeneracy with other parameters in the model. These results are also in good agreement with the previous study using similar galaxy catalog (Y. Song et al. 2025a). The δ_{cen}^i parameters, ranging from about -0.8 to -0.6 , are consistent with expectations from our 2D void identification procedure.

In Figure 7, we present the constraints on the void bias parameters from the void-lensing analysis for the six tomographic bins, which are shown as contour maps and 1D PDFs. We find that the best-fitting values and errors of the six tomographic bins are $b_v^1 = 1.21^{+0.23}_{-0.47}$, $b_v^2 = 1.25^{+0.22}_{-0.47}$, $b_v^3 = 1.63^{+0.30}_{-0.65}$, $b_v^4 = 1.65^{+0.30}_{-0.61}$, $b_v^5 = 1.55^{+0.33}_{-0.60}$, and $b_v^6 = 2.46^{+0.56}_{-1.1}$, which show an increasing trend as redshift increases.

The 1D PDFs of the redshift shift bias Δz^i , stretch factor σ_z^i and multiplicative error m^i are shown in Figure 8. The vertical dotted lines mark the fiducial values of these parameters, while the gray dashed curves represent the Gaussian priors of m^i . Among these systematic parameters, the stretch factor is relatively well constrained, whereas the constraints on the other two systematic parameters are relatively weak and prior domi-

Figure 8. The 1D PDFs of the systematic parameters Δz^i , σ_z^i and m^i for the CSST void-lensing constraints in a 100 deg^2 survey area for the six tomographic bins. The vertical dotted lines mark the fiducial values of these parameters and the gray dashed lines represent the Gaussian priors.

nated. This can be attributed to the limited survey area and the relatively low statistical power of the dataset used in this work. As demonstrated in previous theoretical studies, the constraint precision on these systematic parameters is expected to improve significantly with the full CSST survey (Y. Gong et al. 2019; H. Miao et al. 2023; H. Lin et al. 2022, 2024). For the noise term, we obtain consistent constraint results, with $\log_{10}(N_{\nu\kappa}^{ij}) \simeq -10$ across all redshift bin combinations (i, j) .

5. SUMMARY

In this work, we investigate the cosmological constraints from the void-lensing cross-correlation assuming the w CDM model for the CSST photometric survey. We construct a mock galaxy catalog covering a sky area of 100 deg^2 based on the Jiutian simulations, incorporating the instrumental characteristics and survey strategy of the CSST photometric survey. We divide the galaxy sample into seven photo- z tomographic bins and identify 2D voids in the angular distribution of galaxies within each bin using the Voronoi tessellation and watershed algorithm. We then measure the angular cross-power spectrum between the void distribution and the weak lensing convergence field. The covariance matrix is estimated using the jackknife resampling method combined with the pseudo- C_ℓ approach to account for the partial sky correction. For the theoretical modeling, we employ the HVDM to model the void-matter cross-power spec-

trum and adopt the HSW to describe the void density profile.

After obtaining the mock data, the MCMC technique is employed in the fitting process. We find that the best-fitting values of the cosmological parameters are consistent with the fiducial values within 1σ CL. The constraint strength of some cosmological parameters is comparable to or even better than that obtained from the weak lensing only analysis (Q. Xiong et al. 2025), which used the same mock galaxy catalog. These results demonstrate that the void-lensing serves as an effective cosmological probe and a valuable complement to galaxy photometric surveys, particularly for the forthcoming Stage-IV surveys like CSST.
